

DISTRIBUTION, MOVEMENTS, AND HABITAT USE OF RAZORBACK SUCKER (*XYRAUCHEN TEXANUS*) IN A LOWER COLORADO RIVER RESERVOIR, ARIZONA-NEVADA

Gordon Mueller¹, Paul C. Marsh², Glen Knowles³, and Ty Wolters⁴

ABSTRACT.—Distribution, movements, and habitat use of 10 wild adult razorback suckers (*Xyrauchen texanus*) were examined in Lake Mohave, Arizona-Nevada, from November 1994 through July 1997. Movement rates (0.00–17.35 km d⁻¹) and ranges (\bar{x} = 39 km) were similar to those for riverine populations. All study fish returned to spawning sites used in previous years, but they also visited other spawning areas. Spawning females were significantly ($P = 0.031$) more active than males (480 vs. 87 m d⁻¹) and moved substantial distances between spawning sites during peak reproduction (1–28 February). Fish became most active (m d⁻¹, km month⁻¹) after spawning and moved to areas known to support higher algal production. Fish were typically within 50 m ($P < 0.001$) of shore and at average depths between 3.1 and 16.8 m (range 0.2 to >30.0 m). Adults were detected throughout the available thermal gradient (12°–30°C), but during summer typically had body temperatures between 18° and 22°C. Vertical movements within the water column showed no correlation with depth or time of day, but seasonal shifts suggest fish may regulate body temperature by seeking specific temperatures during reservoir stratification.

Key words: *Xyrauchen texanus*, razorback sucker, reservoir, spawning, habitat, movements, telemetry.

Xyrauchen texanus, the razorback sucker, is the largest catostomid in North America and is endemic to the Colorado River basin. Historically common, this riverine species now is reduced to relic and fragmented populations; 3 of 4 known populations (>100 fish) are in reservoirs (Minckley et al. 1991, Modde et al. 1996, Holden et al. 1997), the largest located in Lake Mohave, Arizona-Nevada. It was listed by the U.S. Fish and Wildlife Service as an endangered species in 1991 (USFWS 1991).

Telemetric research has focused primarily on rivers where adults have been found to use backwater and other lentic type habitats (Tyus 1987, Marsh and Minckley 1989, Modde and Wick 1997). However, riverine monitoring has been hampered by problems associated with working in large, remote systems, a scarcity of wild fish, and a short (2–3 wk) spawning season that occurs on the ascending limb of spring runoff (Tyus 1987, Minckley et al. 1991). Published reports specific to lentic environments are limited to McAda and Wydoski's (1980) description of *X. texanus* use of a gravel pit adjacent to the Colorado River in Colorado and Medel-Ulmer's (1983) abstract describing

X. texanus movement in Senator Wash Reservoir in California. While information is scarce, backwater and floodplain habitat is viewed as critical for species restoration (Valdez and Wick 1981, Wydoski and Wick 1998). The following report presents telemetry data describing *X. texanus* distribution, movements, and habitat use in a Colorado River mainstem reservoir and provides new information on spawner movements and female use of multiple spawning sites.

STUDY AREA

Lake Mohave is a mainstem Colorado River reservoir created with the construction and closure of Davis Dam located 5 km upstream of Laughlin, Nevada. The reservoir borders both Arizona and Nevada and extends 100 km upstream to the tailrace of Hoover Dam. When full (surface elevation 197 m/msl) the reservoir has a surface area of 11,655 ha. The reservoir inundates Black Canyon, located immediately downstream of Hoover Dam, and Pyramid Canyon where Davis Dam was constructed. Between these canyons the reservoir broadens, forming Cottonwood Basin, which

has a maximum width of 6 km (Fig. 1). Lake Mohave has no tributaries other than the Colorado River, which enters as cold, hypolimnetic releases (Lake Mead) from Hoover Dam. Flows are discernible for the first 20–30 km, at which point the river exits Black Canyon and the reservoir broadens and depth increases. Maximum depth at Davis Dam is 35 m.

Construction of Davis Dam in 1954 represented the last mainstem reservoir built on the lower Colorado River. It is believed the reservoir population of *X. texanus* originated from an initially high period of recruitment from individuals trapped upstream during the closure of Davis Dam (Minckley 1983, Marsh 1994).

METHODS

Collections

A trammel net (2 m × 3.7 cm × 50 m) was used to capture wild adult *X. texanus* on 6–7

November 1994 from Lake Mohave at Yuma and Tequila coves. Each fish was measured for total length (mm), weighed (g), anesthetized with tricaine methanesulfate (125 mg L⁻¹), and surgically implanted (after Tyus 1987) with a sonic transmitter. A 30- to 40-mm medio-lateral incision was made slightly anterior and dorsal to the left pelvic fin, and the transmitter was inserted into the abdominal cavity so that it rested on the pelvic girdle. The incision was sutured with 4–5 knots using 3-0 Ethilon black monofilament nylon and an FS-1 cutting needle. We allowed the fish to recover 1–10 min after surgery and then released them at capture sites. Transmitters weighed 6 g, measured 16 × 55 mm, had a 14-month life expectancy, and were individually coded. Transmitters had an average detection range of 1 km and logged the transmitter (fish) temperature ($\pm 0.25^\circ\text{C}$) that was compared with water temperature profile data to determine fish depth.

Fig. 1. Segmented map of Lake Mohave, Arizona-Nevada, showing numbered GPS way-point locations and place names mentioned in the text. Shaded areas reflect total number of fish detections per way-point from November 1994 through July 1997.

Survey Design

We conducted weekly surveys by boat using a global positioning system (GPS) and a preestablished survey grid composed of 71 way-points or "listening stations" programed into a GPS navigational system (Fig. 1). Sites were at <1600-m intervals to standardize search effort and ensure systematic coverage of the reservoir. Transmitter signals were detected using a DH-2 hand-held, directional hydrophone, a USR-5W ultrasonic receiver, and headphones. When signals were detected from way-points, we searched out the exact location and further triangulated using the hydrophone and GPS. A digital readout provided time interval measurements between signals that correlated to tag (fish) temperature. Recorded data included fish location (latitude and longitude), body temperature, and estimated distance (<10 m, 10–50 m, 50–100 m, >100 m) from shore. Vertical water temperature profiles were measured using a Hydro-lab™ temperature profiler between May and October 1995.

Surveys were scheduled biweekly for the 14-month transmitter life and were conducted in 2 shifts: 0200–1000 h and 1400–2200 h. Transmitter life greatly exceeded manufacturer estimates, allowing us to collect additional intermittent information between April and August 1996 and from April through July 1997.

Data Analysis

Using digitized shoreline profile maps of Lake Mohave and the geographical information system (GIS) program ARCINFO™, we created movement maps and calculated distances (m) and movement rates (m d^{-1}) between detection locations. Rate measurements and distances from shore were transformed into single classification frequency distributions, and observed data were summarized by classes. Shoreline use was examined by comparing percentiles of available surface habitat to the percentile of fish use within specific zones via a chi square test ($P < 0.001$; Sokal and Rohlf 1981). Comparisons of shoreline habitat utilization, movement rates, and area affinity were divided into spawning (November–April) and nonspawning (May–October) periods as defined by reports for *X. texanus* in Lake Mohave (Minckley 1983, Bozek et al. 1990, Minckley et al. 1991). Active spawning

was determined through observations and the collection of newly emergent larval *X. texanus* by an independent program (Mueller 1995). Movement rates (m d^{-1}) during active spawning (31 January–15 March 1995, 1996) for both sexes were examined for differences in movement patterns and distances using an analysis of variance ($P < 0.05$; Sokal and Rohlf 1981). To compare male and female movement patterns when spawning observations and larval sucker densities were most prevalent, we mapped individual fish movement during peak spawning (1–28 February).

RESULTS

A total of 20 *X. texanus* (10 males and 10 females) were surgically implanted with sonic transmitters. Six females and 4 males were tracked during the entire 14-month study period and were used in this analysis (Table 1; see Mueller et al. 1998). Remaining fish were excluded from analysis because either we lost contact during the study period or transmitters became immobile (shed tag or mortality). An expanded description can be found in Mueller et al. (1998). Study fish averaged 609 mm (555–680 mm) total length and 2.78 kg (1.75–4.21 kg). More than 1000 contacts were recorded representing 580 daily fish sightings, 300 hourly sightings, 800 body temperatures, and 100 vertical water temperature profiles.

Distribution

Fish distribution was distinctly seasonal. Some areas of the reservoir were occupied year-round, while other locations were used specifically for spawning or as summer sanctuaries. Big Basin and Owl Point areas (Fig. 1) were used year-round; Tequila and Yuma coves and the warm/cold mixing zone were used seasonally. Fish were seldom detected in up- or down-reservoir canyon habitats. Detection numbers were highest between way-point (WP) 30 and WP 37. Fish found in Big Basin typically were along the Nevada shoreline between Nine Mile and Six Mile coves (Fig. 2). This area was used by 3 fish during spawning and by 5 during summer. Tequila Cove (WP 39) was visited by all but 1 fish during spawning.

Owl Point (WP 32) was visited by all spawners and by 4 fish during summer and autumn. Following spawning, 7 suckers moved into the area between WP 12 and WP 24

where cold Hoover Dam releases mix with warmer Lake Mohave waters. We observed 9 *X. texanus* (nontagged) near the surface at the mixing zone on 8 June 1997 (9 fish per 1.5 km).

Movements

Fish movements were variable and distinctive by sex and among individuals. Both males ($>17.4 \text{ km d}^{-1}$) and females (10.1 km d^{-1}) traveled substantial distances in short periods of time, while some fish remained sedentary for days. Fish on average moved 527 m d^{-1} ($\bar{x} = 242\text{--}788 \text{ m d}^{-1}$), and while there was no statistical difference between sexes, females tended to be slightly more active ($\bar{x} = 582 \text{ m d}^{-1}$) than males ($\bar{x} = 446 \text{ m d}^{-1}$; Table 1). Hourly movement rates were statistically examined, and although no significant trends were identified, apparently fish might be slightly more active during summer at midmorning hours (0900–1000 h), supporting previous observations (McAda and Wydoski 1980).

Movement rates were examined both for nondirectional (m d^{-1}) and directional (linear km month^{-1}) activities. Monthly averages near the end of, or shortly after, spawning (March, April, May) exceeded 1000 m d^{-1} for 1995, 1996, and 1997 (Table 2). Linear distances traveled (km month^{-1}) peaked following spawning for all 3 yr (March 1995, May 1996, April 1997 [Table 2]). Linear ranges for indi-

viduals ($N = 10$) averaged 39 km (18–72 km) during the course of the study. Females on average ranged 42 km (29–72 km) compared to 35 km (18–51 km) for males.

All study fish returned to spawning sites used in previous years, but they also visited other spawning sites. Spawning (31 January–15 March 1995, 1996) females were significantly (ANOVA/ $F_{1,8} = 6.79$, $P = 0.0314$) more active (460 vs. 87 m d^{-1}) than males. During peak spawning (1–28 February 1995, 1996), the majority of females crossed the reservoir to visit other spawning sites while males typically remained at a single site (Fig. 2).

Habitat Use

Xyrauchen texanus exhibited a significant association with inshore ($<50 \text{ m}$ of shore) habitats ($P < 0.001$, chi square test). This affinity was most pronounced during spawning when distance from shore averaged $<30 \text{ m}$. Fish moved offshore during summer (July–November), possibly to avoid warmer water temperatures (Fig. 3).

During warmer months the reservoir presented fish a wide range of thermally stratified habitats. Temperatures up-reservoir were cold ($12^{\circ}\text{--}16^{\circ}\text{C}$), regardless of season or depth, due to hypolimnetic releases from Lake Mead. During summer the reservoir thermally stratifies further downstream presenting temperatures ranging from 30°C (surface) to 15°C

Fig. 2. Location and movements of male and female *Xyrauchen texanus* in association with major spawning areas during peak spawning (1–28 February 1995, 1996) in Lake Mohave, Arizona-Nevada.

(depths >30 m). Fish body temperatures ranged between 12° and 28°C, with summer averages ranging from 18° to 22°C, which was similar to thermal preferences reported by Bulkley and Pimentel (1983). Hourly data indicated fish moved vertically in the water column, but we found no correlations for depth with time of day.

Vertical temperature profiles ($n = 107$) were taken from May through November 1995 to correlate body temperature with depth. Fish ranged to depths >30 m but typically were found near 9 m ($\bar{x} = 9.1$ m; Fig. 3). Average fish depths changed with season, suggesting

fish may regulate body temperature during reservoir stratification (Fig. 3). Fish were found nearer the surface during spring and autumn and deeper during midsummer.

DISCUSSION

Lake Mohave scarcely represents what many would consider pristine *X. texanus* habitat. However, it is noteworthy that 3 of 4 remaining wild populations (>100 individuals) are found in reservoirs (Minckley et al. 1991, Holden et al. 1997, Modde and Wick 1997). Investigators who have conducted research in riverine environments have been challenged

by fish scarcity, logistics associated with river hydraulics, sampling in remote areas, and poor water visibility (Tyus 1987, Tyus and Karp 1990, Modde and Irving 1998). On the other hand, researchers working in reservoir environments are presented with a broader and less fluctuating range of physical parameters not found in natural river settings. For instance, reservoir water visibility (>10–15 m) allowed direct observations, summer water temperatures presented a stable but wide thermal gradient (12°–30°C), flows ranged from 0 to 2 m sec⁻¹, depths exceeded 40 m, and fish could choose both littoral and pelagic habitats. Reservoir conditions allowed us to observe spawning and document reproduction through the collection of larval *X. texanus* (Mueller 1989, Minckley et al. 1991, Mueller 1995). River studies have not shared in this degree of documentation, and spawning typically has been inferred by transmitter movement and in a few cases by collection of ripe fish (Tyus 1987, Tyus and Karp 1990, Modde and Irving 1998).

It has been widely reported that *X. texanus* migrate to specific spawning areas (Tyus 1987,

Tyus and Karp 1990, Modde and Irving 1998), and while spawning site fidelity has been speculated, it has never been proven (Tyus and Karp 1990, Scholz et al. 1992, and Modde et al. 1996). Recently, Modde and Irving (1998) speculated *X. texanus* may use multiple spawning sites in the Green River; however, this was not documented by observation or collection of gametes or larvae.

Adult *X. texanus* in Lake Mohave typically used broad, shallow shoreline habitats and generally did not occupy deeper canyon habitat typical of the lower or upper reservoir. Fish were seldom found together except during spawning (McAda and Wydoski 1980) and exhibited movement rates and ranges similar to those in riverine habitats (Tyus 1987, Tyus and Karp 1990, Modde and Irving 1998). Individual fish exhibited various degrees of sedentary and roaming behavior similar to other stream fish (Funk 1955).

Xyrauchen texanus spawning in reservoirs occurs from January through March, which is earlier and typically 2–3 times longer than riverine spawning (Minckley 1983, Minckley et al. 1991). Highly social, these fish form

Fig. 3. Monthly comparison of average depth (m) and body temperature ($^{\circ}\text{C}$) of *Xyrauchen texanus* during thermal stratification (May–October) of Lake Mohave, Arizona-Nevada, in 1995.

spawning groups that can number in the hundreds. Males typically dominate (2:1) spawning sites (Minckley 1983). Females normally join males from adjacent deeper waters when ready to release their eggs (Minckley 1983, Mueller 1989), a behavior common with other catostomids (Moyle 1976).

Prolonged spawning combined with excellent observation and field conditions allowed us to more closely examine spawning and post-spawning movements. All study fish returned to spawning sites used the previous year, although they were also tracked to other spawning groups. In some cases the distance between spawning sites exceeded 50 km; 9 of 10 fish were found crossing the reservoir, participating in spawning groups on both the Arizona and Nevada shorelines. Fish movements during peak spawning (1–28 February 1995, 1996) suggested males typically remain on specific spawning sites while females roam substantial distances between spawning sites. We were unable to determine whether females spawned at multiple sites, but reports of females spawning over extended periods combined with the species known fecundity (>100,000 ova; Minckley 1983, Minckley et al. 1991) support the contention that multiple-site spawning occurs. Multiple-spawning-site behavior also helps explain the high genetic diversity of this population (Dowling et al. 1996).

Travel distances and movement rates peaked post-spawning as the majority (70%) of study fish moved immediately up-reservoir to the warm/cold water mixing zone where nutrient-rich hypolimnetic releases from Lake Mead stimulate algal production (Baker and Paulson 1980). Post-spawning movement supports earlier speculations that *X. texanus* historically

moved to more productive habitats following spawning (Valdez and Wick 1981, Tyus and Karp 1990, Modde and Wick 1997). Increased activity (Table 2) in shallower depths (Fig. 3) may indicate planktonic feeding (Marsh 1987). Wydoski and Wick (1998) suggested floodplain habitats and associated feeding activity are critical for fish to regain body condition after spawning.

Homing patterns of spawning and non-spawning populations were typical of those described by Gerking (1958): "Spawning migrations are directed toward a specific location . . . [while] the fish are usually scattered over a wide area during the non-reproductive portion of life." While fish used common areas during spawning, they typically dispersed after spawning, with some fish returning to specific locations in which they had been found the previous summer. The distance between spawning and summer use areas ranged from 20 km (4 fish) to 30 km (6 fish), with no correlations with sex or size. Fish exhibited a great deal of individuality, some being quite active while other were quite sedentary and remained in specific coves for weeks.

ACKNOWLEDGMENTS

We thank numerous colleagues: Tom Burke (Bureau of Reclamation), Kent Turner (National Park Service), and George Devine (U.S. Fish and Wildlife Service) contributed initial review and administrative support; Tom Burke provided larval fish data; numerous National Park Service staff assisted in field surveys; Mike Burrell (Nevada Department of Wildlife) collected study adults; Bob Waltermire helped analyze GIS and GPS data; and the Bureau of Reclamation supplied field equipment and logistical support. We thank Tim Modde and Dennis Shiozawa for reviewing the manuscript. Work was conducted under appropriate state and federal permits and was funded by U.S. Geological Survey.
